Anterior Crown Troughing With the AMD Picasso Lite Diode Laser

By Dr. Glenn van As

Introduction:

In July's clinical technique article, I dealt with the role of the diode laser in the tissue management portion of the fabrication of posterior indirect restorations. As I mentioned last month, Gherione et al (1) found lasers to yield less recession than using either a double retraction cord or electrocautery technique for tissue management. Their conclusion was that the laser was "less traumatic to the periodontal tissues" when compared to the traditional techniques of using either retraction cords or an electrosurgery.

For new laser users, my advice is to start with posterior crown troughing, and after a few cases then turn to using the diode in the anterior region. In my opinion, careful attention to detail is required when using the diode laser for anterior tissue troughing, and there are specific adjustments that should be undertaken. These adjustments are particularly important when esthetics in the context of the patient's demands or alterations in the shade of the final restoration as compared to the stumpy shade of the preparation.

Technique:

When considering using the diode laser for tissue management in the anterior esthetic zone where thin tissue gencotypes exist, or if the patient is changing the color of the tooth significantly from the existing stumpy shade, then care with diode troughing must be taken. Goharian et al concluded that the diode laser has a "remarkable cutting ability and the tolerable damage area" and due to its "excellent coagulation ability" it is useful alternative in soft tissue surgery of the oral cavity(2).

There is a risk of tissue recession to any tissue retraction technique so the clinician must evaluate the individual risk prior to beginning. Generalized recession in the premolar area, recession around existing restoration margins, non-stopped gingival tissues and the presence of gingival inflammation (pseudo pockets) can all be warning signs that careful handling of gingival tissues regardless of technique is indicated in order to prevent iatrogenic damage to the gingival tissue complex.

As mentioned last month adequate magnification (4.0 X Loupes) and judicious use of power (5.0-10.0 w CW) are vital to success in laser troughing. Another option to low settings is to use a pulsed mode of laser energy on the tissue. (Comfort Mode on AMD Lasers Picasso Lite). Pulsing the laser means shaping up the continuous beam of light, and gives time between pulses to cool the tissue down.

Prior to beginning with preparation of the teeth, the diode laser can be used to provide idealized soft tissue contours. Slight attentions in tissue height and/or tissue symmetry can be accompanied with the diode as long as these attentions do not infringe upon the biologic width of the sulcus. These subtle attentions to the soft tissue can improve the final result and be completed on the same day as final impressions for the restorations are completed.

Subsequently, the initial crown or veneer preparations are completed and the properly stripped, cleaved and initiated quartz fiber tip (or single use initiated disposable dpj is extended just into the gingival sulcus 0.5-1.0 mm) (fig. 1).

The laser is moved in small brush like strokes around the preparation, creating a slight distortion of the tissue away labially away from the margin of the preparation. This lateral distortion is not intended to lower the height of the tissue like a gingivectomy would but simply create a "moat" which separates tooth from soft tissue. This separation allows for room for the impression material to capture details of the margin location.

Troughing for a veneer (20-40 seconds) should take less time than a full crown preparation (30-90 seconds) and careful analysis of the laser-tissue interaction should reveal minimal to no changing of the soft tissue, which causes postoperative discomfort and gingival recession. After the initial laser trough has been completed, the clinician places the final restorative margins on solid tissue structure or slightly subgingivally on the facial for esthetics as needed. Hydrogen Peroxide in a Dental InfraRed (UD) or a wet cotton pellet can be accumulated on the soft tissue to remove any white tissue tags which may accidentally droop onto the margin. Increased lateral distortion of the tissue trough can be accomplished with materials like Exepal or Triscord injected briefly into the sulcus. Vigorous urging of the sulcus after 90-120 seconds will yield a clean, dry and well delineated margin and the final impression can be taken. Provisional restorations should be evaluated to make sure that they do not extend into the sulcus (especially important on the facial of the temporary restoration(s) which can iatrogenically cause the tissue to recede. Careful removal of temporary cement completes the initial appointment.

The patient returns for final insertion of the definitive restorations in 15-14 days and upon removal of the provisional, the tissue appears healthy, and situated exactly where the laser troughing placed it at the first appointment. In cases of poorly fitting provisional crowns, some soft tissue "bounce back" leading to the margin being covered by soft tissue. The diode laser with topical (Cyclohex) and settings of 0.6-0.8 watts (CW) can be used to remove any soft tissue overhanging the margins and the crown can be tried in and cemented. With careful attention to detail the results can be identified to those obtained with traditional methods (see case below) and the diode laser will become an indispensable part of the soft tissue management and impression taking for fixed prosthodontics.
